Copper; EIS; EFM; Quantum chemical calculation; Molecular modeling

Abstract Electrochemical frequency modulation (EFM), electrochemical impedance spectroscopy (EIS) and potentiodynamic polarization have been used to investigate the inhibition effect of a new pyrimidine heterocyclic derivative, namely 2-mercapto-4-(p-methoxyphenyl)-6-oxo-1,6-dihydropyrimidine-5-carbonitrile (MPD) on copper corrosion in 3.5% NaCl solutions at 25 ± 1°C. The electrochemical investigations showed that MPD gives sufficient inhibition against copper corrosion in 3.5% NaCl solutions. Potentiodynamic polarization measurements have shown that the MPD inhibit both the cathodic and anodic processes and thus it classified as mixed-type inhibitor. EIS measurements indicate that the values of constant phase elements (CPEs) tend to decrease and both charge-transfer resistance and inhibition efficiency tend to increase by increasing the inhibitor concentration. Electrochemical kinetic parameters obtained using EFM methods were comparable with that calculated from traditional measurements (EIS and potentiodynamic polarization). Molecular
1. Introduction

Copper and its alloys are industrial materials with a wide variety of applications due to electrical, thermal, mechanical and corrosion resistance properties. However, in the presence of oxygen, chlorides, sulphates or nitrates ions, they are exposed to localized corrosion (Vera et al., 1995; Rosales et al., 1999; Cantor et al., 2006). It is widely used in many applications in electronic industries and communications as a conductor in electrical power lines, pipelines for domestic and industrial water utilities including sea water, heat conductors, heat exchangers, etc. Therefore, corrosion of copper and its inhibition in a wide variety of media, particularly when they contain chloride ions, have attracted the attention of many investigators (Hoepner and Lattemann, 2003; Sherif and Park, 2005; Qu et al., 2005; Singh et al., 2003; Bellakhil and Dachraoui, 2004; Lee and Nobe, 1986; Wang et al., 2004; Kendig and Jeanjaquet, 2002).

The corrosion of copper and its alloys depends to a great extent on the composition of the electrolyte in contact with the metal surface. The process involves copper dissolution at local anodic sites and electrochemical reduction of some species such as oxygen at cathodic areas. In chloride solutions, the first step of the anodic dissolution is the formation of complex CuCl₂⁻. In addition, it was found that during anodic polarization, there is always equilibrium between a thin layer of CuCl and a dense layer of dissolved CuCl₂⁻ (Crousier et al., 1988). In natural fresh water, protecting coatings, such as Cu₂O and Cu(OH)₂ are formed on copper. These layers influence electrochemical processes at copper electrodes (Bertoceci and Turner, 1974; Van Muydier, 1981; Speckmann and Strehblow, 1984).

The role of Cl⁻ ions in copper corrosion in NaCl centered around (i) a competitive adsorption with OH⁻ on the available Cu surface, thus creating sites that are more liable for electrochemical dissolution, and (ii) competition with OH⁻ attached to Cu(II) ions in a soluble intermediate stage, thus enhancing film rupture through dissolution (Cicleo et al., 1998).

The inhibition action of certain organic compounds on metallic corrosion processes has been extensively studied in recent years (Granese et al., 1992; Cicleo et al., 1995; Mansfeld and Wang, 1995; McMahon and Harrop, 1995; Brunoro et al., 1975; Raicheva et al., 1980). There is an agreement of some stages participating in the overall inhibition process, particularly with respect to the mechanism in which inhibition occurs.

Currently, research in copper corrosion is oriented to the development an effective and safe corrosion inhibitors in order to reduce the use of chromates (Mansfeld and Wang, 1995; McMahon and Harrop, 1995; Saleh et al., 1983). In addition heterocyclic organic compounds have generally been used as corrosion inhibitors due to their high inhibition efficiency.

In this study we have investigated the ability of 2-mercapto-4-(p-methoxyphenyl)-6-oxo-1,6-dihydropyrimidine-5-carbonitrile (MPD) to inhibit copper corrosion in 3.5% NaCl solution. Electrochemical methods, quantum chemical calculations and molecular dynamic simulations were used to study the interaction between MPD and the copper surface in 3.5% NaCl.

2. Experimental

In this study a new pyrimidine heterocyclic derivative, namely 2-mercapto-4-(p-methoxyphenyl)-6-oxo-1,6-dihydropyrimidine-5-carbonitrile (MPD) was prepared in our laboratory where a mixture of 2-cyano-3-(p-methoxyphenyl) prop-2-enoate (0.01 mol), thiourea (0.01 mol), anhydrous K₂CO₃ (0.03 mol) in ethanol (30 ml) was heated under reflux for 3 h. The precipitate obtained was washed with water and crystallized from ethanol to give MPD; its structure was confirmed with different spectroscopic techniques (Ram et al., 1984) and presented below:

![Spectral image](image_url)

The MPD is added to the 3.5% NaCl at concentrations of 5 × 10⁻³, 10⁻⁴, 5 × 10⁻⁵ and 10⁻³ M.

Cylindrical rods of copper specimens obtained from Johnson Mattey (Puratronic, 99.999%) were mounted in Teflon. An epoxy resin was used to fill the space between Teflon and copper electrode. The circular cross sectional area of the copper rod exposed to the corrosive medium, used in electrochemical measurements, was (0.28 cm²).

The electrochemical measurements were performed in a typical three-compartment glass cell consisted of the copper specimen as working electrode (WE), platinum counter electrode (CE), and a saturated calomel electrode (SCE) as the reference electrode. The counter electrode was separated from the working electrode compartment by fritted glass. The reference electrode was connected to a Luggin capillary to minimize IR drop. Solutions were prepared from bidistilled water of resistivity 13 MΩ cm, the copper electrode was abraded with different grit emery papers up to 4/0 grit size, cleaned with acetone, washed with double-distilled water and finally dried.
Tafel polarization curves were obtained by changing the electrode potential automatically from −800 to +300 mV SCE at open circuit potential with scan rate of 1.0 mV s⁻¹. Impedance measurements were carried out in frequency range from 100 kHz to 40 mHz with an amplitude of 10 mV peak-to-peak using ac signals at open circuit potential. Electrochemical frequency modulation, EFM, was carried out using two frequencies 2 Hz and 5 Hz. The base frequency was 1 Hz, so the waveform repeats after 1 s. The higher frequency must be at least two times the lower one. The higher frequency must also be sufficiently slow so that the charging of the double layer does not contribute to the current response. Often, 10 Hz is a reasonable limit.

The electrode potential was allowed to stabilize 60 min before starting the measurements. All experiments were conducted at 25 ± 1 °C. Measurements were performed using Gamry Instrument Potentiostat/Galvanostat/ZRA. This includes a Gamry Framework system based on the ESA400, Gamry applications that include del105 for dc corrosion measurements, EIS300 for electrochemical impedance spectroscopy and EFM 140 for electrochemical frequency modulation measurements along with a computer for collecting data. Echem Analyst 5.58 software was used for plotting, graphing and fitting data.

3. Computational details

The correlation between theoretically calculated properties and experimentally determined inhibition efficiencies has been studied successfully for uniform corrosion (Vosta and Eliasekk, 1971; Chakrabarti, 1984; Abdul-Ahad and Al-Madfai, 1989; Growcock, 1989; Costa and Lluch, 1984; Kutej et al., 1995; Lukovits et al., 1995, 1999; Awad et al., 1997; Bereket et al., 2001, 2002). Several theoretical parameters include the electronic properties of inhibitors, effects of the frontier molecular orbital energies, the differences between lowest unoccupied molecular orbital (LUMO) and highest occupied molecular orbital (HOMO) energies (E_L - E_H), electronic charges on reactive centers, dipole moments and conformation of molecules have been investigated by semi-empirical methods. First step for calculating the theoretical parameters of the studied molecule is the geometry optimization process which is carried out using an iterative process, in which the atomic coordinates are adjusted until the total energy of a structure is minimized, i.e., it corresponds to a local minimum in the potential energy surface. Interaction between MPD and Cu (1 1 1) surfaces was the negative value of the interaction energy (Mineva et al., 2001), as follow:

\[
E_{\text{binding}} = -E_{\text{Cu-inhibitor}}
\]

Several traditional corrosion techniques implied to study the corrosion inhibition of copper by MPD in 3.5% NaCl solutions to evaluate the electrochemical kinetic parameters obtained by using electrochemical frequency modulation as a new technique that can be used to calculate the corrosion rate of a metal without a prior knowledge of Tafel slopes. Potentiodynamic polarization and electrochemical impedance spectroscopy, EIS measurements are used to calculate the inhibition efficiency as well as other corrosion kinetic parameters.

4. Results and discussion

4.1. Experimental measurements

Several traditional corrosion techniques implied to study the corrosion inhibition of copper by MPD in 3.5% NaCl solutions to evaluate the electrochemical kinetic parameters obtained by using electrochemical frequency modulation as a new technique that can be used to calculate the corrosion rate of a metal without a prior knowledge of Tafel slopes. Potentiodynamic polarization and electrochemical impedance spectroscopy, EIS measurements are used to calculate the inhibition efficiency as well as other corrosion kinetic parameters.

4.1.1. Electrochemical frequency modulation, EFM

The result of EFM experiments is a spectrum of current response as a function of frequency. The spectrum is called the 'intermodulation spectrum'. Fig. 1 shows the corresponding current response in the intermodulation spectrum for copper in aerated 3.5% NaCl solutions at 25 ± 1 °C.

Electrochemical kinetic parameters calculated from EFM for copper in 3.5% NaCl are listed in Table 1 and calculated using the following Eqs. (3–7):

\[
i_{\text{corr}} = \frac{q_{io}}{\sqrt{48(2i_{io}l_{io} - i_{io})}}
\]

\[
\beta_a = \frac{i_{ao}U_o}{2l_{ao} + 2\sqrt{3}l_{2ao} - q_{io}^2}
\]

\[
\beta_0 = \frac{i_{0o}U_o}{2\sqrt{3}(l_{2ao} - q_{io}^2 - 2l_{ao})}
\]

Causality factor (2) = \frac{i_{ao,\text{kin}}}{i_{ao,\text{tot}}} = 2.0

Causality factor (3) = \frac{i_{0o,\text{kin}}}{i_{0o,\text{tot}}} = 3.0
where \( i \) is the instantaneous current density at the working copper electrode measured at frequency \( \omega \) and \( U_o \) is the amplitude of the sine wave distortion.

Table 1 shows the corrosion kinetic parameters such as inhibition efficiency (\( E_{EFM}\% \)), corrosion current density (\( \mu A \text{ cm}^{-2} \)), Tafel constants (\( \beta_a, \beta_c \)) and causality factors (CF-2, CF-3) at different concentration of MPD derivative in 3.5% NaCl at 25 ± 1 °C.

It is obvious from Table 1 that, the corrosion current densities decrease by increasing the concentrations of these
The inhibition efficiencies increase by increasing MPD concentrations. The causality factors in Table 1 are very close to the theoretical values which according to the EFM theory (Khaled, 2008) should guarantee the validity of Tafel slopes and corrosion current densities. Inhibition efficiency (EEFM\%) depicted in Table 1 calculated from the following Eq. (8):

\[
EEFM\% = \left(1 - \frac{i_{corr}}{i_{corr}\text{'}}\right) \times 100
\]

where \(i_{corr}\) and \(i_{corr}\text{'}) are corrosion current density in the absence and presence of MPD derivative, respectively.

It is clear from Table 1 that the corrosion current densities decrease with increase in MPD concentrations. Values of the causality factors in Table 1 indicate that the measured data are of good quality. The standard values for CF-2 and CF-3 are 2.0 and 3.0, respectively. The causality factors are calculated from the frequency spectrum of the current response. If the causality factors differ significantly from the theoretical values of 2.0 and 3.0, then it can be deduced that the measurements are influenced by noise. If the causality factors are approximately equal to the predicted values of 2.0 and 3.0, i.e. there is a causal relationship between the perturbation signal and the response signal. Then the data are assumed to be reliable (Bosch et al., 2001).

The great strength of the EFM is the causality factors which serve as an internal check on the validity of the EFM measurement (Bosch et al., 2001; Abdel-Rehim et al., 2006). With the causality factors the experimental EFM data can be verified. The standard values for CF-2 and CF-3 are 2.0 and 3.0, respectively. The deviation of causality factors from their ideal values might due to that the perturbation amplitude was too small or that the resolution of the frequency spectrum is not high enough also another possible explanation that the inhibitor is not performing very well. In an attempt to evaluate the EFM technique as an effective corrosion monitoring technique, several traditional techniques implied to study the corrosion inhibition of copper by MPD in 3.5% NaCl media. Both EIS and potentiodynamic polarization techniques are used to calculate the inhibition efficiency as well as other corrosion kinetic parameters.

### 4.1.2. Impedance measurements

The corrosion behaviour of copper in 3.5% NaCl in absence and presence of MPD investigated by EIS after immersion for 1 h at 25 ± 1 °C. Nyquist plots of copper in uninhibited and inhibited sodium chloride solutions containing various concentrations of MPD are presented in Fig. 2.

The shape of the impedance diagrams of copper in 3.5% NaCl is similar to those found in the literature (Khaled, 2008). The presence of MPD increases the impedance but does not change the other aspects of corrosion mechanism occurred due to its addition. Symbols in Fig. 2 represent the measured data and solid lines represent the fitting data obtained using

Figure 2  Nyquist plots for copper in 3.5% NaCl solutions in the absence and presence of various concentrations of MPD at 25 ± 1 °C.
the equivalent circuit (Sherif and Park, 2006) presented in Fig. 3. The parameters obtained by fitting the experimental data using the equivalent circuit, and the calculated inhibition efficiencies are listed in Table 2, where \( R_t \) represents the solution resistance, \( R_p \) is the polarization resistance and can be defined as the charge-transfer resistance, CPE1 and CPE2 are constant phase elements (CPEs), \( R_p \) is another polarization resistance and \( W \) is the Warburg impedance. The Nyquist plots presented in Fig. 2 clearly demonstrate that the shapes of these plots for inhibited copper electrode are not substantially different from those of uninhibited electrode. Addition of MPD molecules increases the impedance but does not change other aspects of the electrode behaviour. Nyquist spectra presented in Fig. 2 are modeled using an equivalent circuit similar to the one proposed by several authors (Juttner et al., 1988, 1986).

The impedance spectra obtained for copper in 3.5% NaCl contains depressed semicircle with the center under the real axis, such behaviour is characteristic for solid electrodes and often referred to as frequency dispersion and attributed to the roughness and other inhomogenities of the solid electrode (Ma et al., 2002; Pajkossy, 1994).

Parameters derived from EIS measurements and inhibition efficiency is given in Table 2. Addition of MPD increases the values of \( R_p \) and \( R_p \) and lowers the values of CPE1 and CPE2 and this effect is seen to be increased as the concentrations of MPD increase. The constant phase elements (CPEs) with their \( n \) values close to 0.5 are represented double layer capacitors with some pores (Sherif and Park, 2006). The CPEs decrease upon increase in MPD concentrations, which are expected to cover the charged surfaces and reducing the capacitive effects.

This decrease in (CPE) results from a decrease in local dielectric constant and/or an increase in the thickness of the double layer, suggested that MPD molecules inhibit the copper corrosion by adsorption at the copper/NaCl interface. The semicircles at high frequencies in Fig. 2 are generally associated with the relaxation of electrical double layer capacitors and the diameters of the high frequency semicircles can be considered as the charge-transfer resistance \( (R_t = R_p) \) Ma et al., 2002. Therefore, the inhibition efficiency, \( \eta \) of MPD for the copper electrode can be calculated from the charge-transfer resistance as follows (Ma et al., 2002):

\[
\eta = \left(1 - \frac{R_p}{R_p}\right) \times 100
\]  

where \( R_p \) and \( R_p \) are the polarization resistances for uninhibited and inhibited solutions, respectively. The CPEs are almost like Warburg impedance with their \( n \) values close to 0.5 in presence of MPD (Sherif and Park, 2006), which suggests that the electron transfer reaction corresponding to the second semicircle takes place through the surface layer and limits the mass transport (Warburg). The presence of the Warburg \( (W) \) impedance in the circuit also confirms that the mass transport is limited by the surface passive film.

4.1.3. Potentiodynamic polarization measurements

Measurements of current-potential values under carefully controlled conditions can yield information on corrosion rates, coatings and films, passivity, pitting tendencies and other important phenomena.

When a copper specimen is immersed in 3.5% NaCl, both reduction and oxidation processes occur on its surface. Typically, the copper specimen oxidizes (corrodes) and the oxygen is reduced. The cathodic reaction of copper in aerated sodium chloride solutions is well known to be the oxygen reduction (Vera et al., 1995; Sherif, 2006)

\[ \text{O}_2 + 2\text{H}_2\text{O} + 4e^- \rightarrow 4\text{OH}^- \quad (10) \]

Any corrosion processes that occur are usually a result of anodic currents. When a copper specimen is not connected to any instrumentation as it would be “in service” the specimen assumes a potential (relative to a reference electrode) termed the corrosion potential, \( E_{\text{corr}} \). The corrosion potential, \( E_{\text{corr}} \) can be defined as the potential at which the rate of oxidation is exactly equal to the rate of reduction (Basics of corrosion measurements, 1982).

The potentiodynamic polarization curves recorded for the copper electrode in the absence and presence of MPD are presented in Fig. 4. As can be seen from Fig. 4 that the anodic branch of Cu in NaCl solutions in the absence and the presence of MPD molecules shows a three distinct regions; firstly, increasing the current from the Tafel region at lower over-potentials, which extending to the peak current density due to the dissolution of copper metal to Cu^+:

\[ \text{Cu} \rightarrow \text{Cu}^+ + e^- \quad (11) \]

Secondly, the region of decreasing currents until a minimum is reached due to the formation of CuCl

\[ \text{Cu}^+ + \text{Cl}^- \rightarrow \text{CuCl} \quad (12) \]

And finally the region of sudden increase in current density leading to a limiting value as a result of CuCl_2 formation which is responsible on the dissolution of Cu

\[ \text{CuCl} + \text{C}^2- \rightarrow \text{CuCl}_2 \quad (13) \]

It is also seen from Fig. 4 that increasing the MPD concentrations, decreases the cathodic, anodic and corrosion currents \( (i_{\text{corr}}) \) and consequently the corrosion rates.

It has been shown that in the Tafel extrapolation method, the use of both the anodic and cathodic Tafel regions is undoubtedly preferred over the use of only one Tafel region (McCafferty, 2005). However, the corrosion rate can also be determined by Tafel extrapolation of either the cathodic or anodic polarization curve alone. If only one polarization curve is used, it is generally the cathodic curve which usually produces a longer and better defined Tafel region. Anodic polarization may sometimes produce concentration effects, due to passivation and dissolution, as well as roughening of the surface which can lead to deviations from Tafel behaviour.

The situation is quite different here; the anodic dissolution of copper in aerated 3.5% NaCl solutions obeys, as previously mentioned, Tafel’s law. The anodic curve is, therefore preferred over the cathodic one for evaluation of corrosion currents, \( i_{\text{corr}} \), by the Tafel extrapolation method. However, the cathodic polarization curve deviate from the Tafel behaviour, exhibiting a limiting diffusion current, may be due to the reduction of dissolved oxygen. Accordingly, there is a source of error in the numerical values of the cathodic Tafel slopes calculated by the software. For this reason, the values of the

cathodic Tafel slopes, calculated from the software, are not included here.

Addition of $10^{-3}$ M of MPD reduces to a great extent the cathodic and anodic currents, $i_{corr}$. The corresponding electrochemical kinetics parameters such as corrosion potential ($E_{corr}$), anodic Tafel slopes ($b_a$) and corrosion current density ($i_{corr}$), obtained by extrapolation of the Tafel lines are presented in Table 3. The inhibitor efficiency was evaluated from dc measurements using the following Eq. (14) (Hack and Pickering, 1991):

$$\eta_{\%} = \left(1 - \frac{i_{corr}}{i_{corr}^o}\right) \times 100$$ (14)

where $i_{corr}^o$ and $i_{corr}$ correspond to uninhibited and inhibited current densities, respectively.

Inspection of Table 3, shows that the addition of different concentration of MPD decreases corrosion current densities and increases the inhibition efficiencies $\eta_{\%}$.

4.2. Molecular dynamics simulations

In an attempt for understanding the interaction between MPD molecules and copper/copper oxide surface, molecular dynamic simulations study have been performed to simulate the adsorption of MPD on the copper surface. Inspection of molecular structure of MPD shows that it is likely to adsorb on copper surface by sharing the electrons of nitrogen, sulfur, oxygen, phenyl rings and pyrimidine structure with copper. The adsorption progress of MPD on copper surface is investigated by performing molecular mechanics (MM) using MS modeling software. The periodic boundary conditions (PBC) were applied to the simulation cell and described elsewhere (Khaled, 2008). MPD molecule was energy optimized, copper surface was constructed using the amorphous cell module, the whole system was energy optimized and the possibility of MPD adsorption on the copper surface were simulated as in Fig. 5. It could be seen from Fig. 5 that MPD molecule move near to the copper surface, indicating that MPD adsorbed at copper surface. Fig. 5 shows that the adsorption occurred through the nitrogen atoms in MPD. During simulation, both in plane aromatic structures are fluctuating up and down the copper surface while nitrogen atoms are attached all the time to copper surface.

The adsorption density of MPD on the Cu (1 1 1) substrate has been presented in Fig. 6. Therefore, the studied molecules are likely to adsorb on the copper surface to form stable adsorption layers and protect copper from corrosion. The binding energies as well as the adsorption energy were calculated and presented in Table 4.

The parameters presented in Table 4 include total energy, in kcal mol$^{-1}$, of the substrate–adsorbate configuration. The total energy is defined as the sum of the energies of the adsorbate components, the rigid adsorption energy and the deformation energy. In this study, the substrate energy (copper surface) is

4.2.1. Quantum chemical calculations

The Mulliken atomic charges distributions of MPD molecule as well as the highest occupied molecular orbitals (HOMO) and lowest unoccupied molecular orbital (LUMO) were calculated using Hyperchem 8.0.7 software and presented in Fig. 6.

It is confirmed that the more negative the atomic partial charges of the adsorbed centre are, the more easily the atom attracted to the metal surface.

Some of the key quantum chemical parameters were computed using the PM3-SCF method and presented in Table 4. These are mainly the energies of the highest occupied (\( E_{HOMO} \)) and lowest unoccupied (\( E_{LUMO} \)) molecular orbitals and total energy (\( E_{tot} \)). These quantum chemical parameters were obtained after geometric optimization with respect to the all nuclear coordinates.

Frontier orbital theory is useful in predicting adsorption centers of the inhibitor molecules responsible for the interaction with surface metal atoms (Fang and Li, 2002; Bereket et al., 2002). Moreover, the gap between the LUMO and HOMO energy levels of the molecules was another important factor that should be considered. Reportedly, excellent corrosion inhibitors are usually those organic compounds which are not only offer electrons to unoccupied orbital of the metal, but also accept free electrons from the metal (Zhao et al., 2005).

It is well established in the literature that the higher the HOMO energy of the inhibitor, the greater the tendency of offering electrons to unoccupied d orbital of the copper ion, and the higher the corrosion inhibition efficiency. In addition, the lower the LUMO energy, the easier the acceptance of electrons from metal surface, as the LUMO–HOMO energy gap decreased and the efficiency of inhibitor improved. Quantum chemical parameters listed in Table 4 reveal that MPD has high HOMO and low LUMO with high energy gap.

The number of transferred electrons (\( \Delta N \)) was also calculated depending on the quantum chemical method as in the following Eq. (15):

\[
\Delta N = \frac{Z_{Cu} - Z_{inh}}{2(\eta_{Cu} + \eta_{inh})}
\]

where \( Z_{Cu} \) and \( Z_{inh} \) denote the absolute electronegativity of copper and the MPD molecule, respectively; \( \eta_{Cu} \) and \( \eta_{inh} \) denote the absolute hardness of copper and the inhibitor molecule, respectively. These quantities are related to electron affinity (\( A \)) and ionization potential (\( I \)) which are useful in their ability to help predict chemical behaviour (Pearson, 1986).

\[
\chi = \frac{I + A}{2}
\]

\[
\eta = \frac{I - A}{2}
\]

\( I \) and \( A \) are related in turn to \( E_{HOMO} \) and \( E_{LUMO} \)

\[
I = -E_{HOMO}
\]

\[
A = -E_{LUMO}
\]

Values of \( \chi \) and \( \eta \) were calculated by using the values of \( I \) and \( A \) obtained from quantum chemical calculation. Using a theoretical \( \chi \) value of 4.48 eV/mol according to Pearsons electronegativity scale and \( \eta \) value of 0 eV/mol for copper (Pearson, 1988), \( \Delta N \), is the fraction of electrons transferred from inhibitor to the copper surface, was calculated. Values of \( \Delta N \) showed inhibition effect resulted from electrons donation. Agreeing with Lukovits’s study (Lukovits et al., 2001), if \( \Delta N < 3.6 \), the inhibition efficiency increased with increasing electron-donating ability at the metal surface. In this study, MPD was the donor of electrons, and the copper oxide surface was the acceptor. MPD was bound to the copper oxide surface, and thus formed inhibitive adsorption layer against corrosion.

The vertical distance, calculated from molecular dynamics, between the flat molecules and copper surface was about 2.1 Å for MPD; this result indicates that the interaction between the MPD molecules and the copper surface is strong enough to inhibit corrosion.

5. Conclusion

The main conclusions of the present study can be summarized as follows.

MPD presents good inhibition efficiency against copper corrosion in 3.5% sodium chloride solutions. Tafel polarization studies have shown that the MPD suppresses both the cathodic and anodic processes and thus it acts as mixed-type inhibitor. EIS measurements indicate that the value of CPEs
tends to decrease and both charge-transfer resistance and inhibition efficiencies tend to increase by increasing the MPD concentration. This result can be attributed to increase of the thickness of the electrical double layer. Electrochemical kinetic parameters obtained from EFM technique are in good agreement with that obtained from traditional electrochemical measurements. Accordingly EFM can be used as a rapid and non-destructive technique for corrosion rate measurements without prior knowledge of Tafel constants. Molecular dynamic simulations and quantum chemical calculations are performed to investigate the adsorption behaviour of MPD on copper surface.

Acknowledgement

The authors’ gratefully acknowledge the inhibitor preparation carried out by Dr. K. M. El-Mahdy, lecturer of organic chemistry, chemistry department, faculty of education, Ain Shams University, Roxy, Cairo, Egypt.
